Keywords: non-proportional bending with torsion, fatigue life, critical plane, random loading.

Abstract. The paper presents comparison of fracture plane position gained from experiment tests of specimens under multiaxial loading and theoretical ones from calculation according to variance and damage accumulation methods. In the variance method it is assumed that the plane in which the maximum variance of the equivalent stress appears is critical for a material and the fatigue fracture should be expected in this plane. In the damage accumulation method as fracture plane, the plane which suffered the greatest damage during service loading is adopted. For both methods the equivalent stress was calculated according to the fatigue failure criterion of maximum normal and shear stresses in the critical plane.

Introduction
To establish the critical plane position two variance and damage accumulation methods were used. The method of variance [1] relies on search of the maximum variance of equivalent stress (or another parameter) according to the selected fatigue failure criterion. The plane where the variance reaches its maximum is assumed as the critical plane. The method of damage accumulation [2, 3] seems to be the most interesting because of its close relation to the idea of critical plane. Here, the selected fatigue failure criterion is applied for search of the plane of the maximum damage, i.e. the plane of the minimum fatigue life. This is an iterative method, so search of the critical plane requires repetition of all the calculation algorithm many times.

The aim of the paper is comparison of the variance method and the method of damage accumulation for determination of the critical plane position with the results of experiments.

Material and test procedure
Specimens of round sections were tested (see Fig. 1a). Those were cut from the sheets 16 mm thick, according to the rolling direction. The specimen surface has been obtained by turning using conventional polishing with progressively finer emery papers. A final average roughness 0.16 μm has been measured. Diameter of the specimens was d = 8 mm for pseudo-random loading. Some mechanical properties under bending of the tested steel are given in Table 1. The tests were performed, in the high cycle fatigue regime (HCF) under pseudo-random bending with torsion loading, at Opole University of Technology [4, 5]. The fatigue stand was used to carry out fatigue tests. The stand MZGS-200PL (pseudo-random loading), with the dominating frequency 28.8 Hz for bending and 30 Hz for torsion, is applied for fatigue tests of specimens made of structural materials subjected to non-proportional combinations of the bending moment MB and the torsional moment MT.
Fig. 1. Shape and dimensions of a specimen a) and definition of the critical plane position with estimated shear fracture plane $\alpha_t$ b).

Histories of these moments are independent (separate drives and control systems) and they are polyharmonic (pseudo-random). The histories are sums of four harmonic components with different amplitudes, frequencies and phases. The stand enables testing of the influence of cross-correlation between normal and shear stresses, their frequencies and amplitudes on the fatigue life of the tested material.

**Experimental results and discussion**

The critical plane position for a given material depends on values of loadings, the cross-correlation coefficient of stresses, and the ratio of maximum stresses. Using mathematical relationships, while calculations one or more positions of the critical plane are obtained. Moreover, material is never perfect and a damage can occur in the point where its structure is heterogeneous. Fig. 1b shows definition of the critical plane position and how the angle $\alpha_t = \alpha_{FP} \pm 45^\circ$ ($\alpha_{FP}$ – average angle of fracture plane position) were determined.

In the present paper, on base of earliest analysis experimental tests [5], the failure criterion of maximum normal and shear stress in the critical plane was assumed for fatigue life calculation. According to this criterion, the equivalent stress $\sigma_{eq}(t)$ in the plane of maximum shear stress $\tau_1(t)$ takes the following form

$$
\sigma_{eq}(t) = (2 - B)\left[\sigma_x(t) \cdot \cos^2(\alpha) + \tau_{xy}(t) \cdot \sin(2\alpha)\right] + B\left[-0.5\sigma_x(t) \cdot \sin(2\alpha) + \tau_{xy}(t) \cdot \cos(2\alpha)\right]
$$

(1)

where: $B = \sigma_{af}/\tau_{af} = 1.73$ (for $N_f = 3.135\cdot10^6$ cycles) – fatigue limits ratio under bending and torsion, respectively, $\sigma_x(t)$ - normal stress along the specimen axis, $\tau_{xy}(t)$ - shear stress in the specimen cross section, $\alpha$ - angle determining the critical plane position (Fig. 1b).

From Eq. (1) it appears that the equivalent stress $\sigma_{eq}(t)$ is linearly dependent on the stress state components $\sigma_x(t)$ and $\tau_{xy}(t)$, so it can be expressed as

$$
\sigma_{eq} = \sum_{j=1}^{n} a_j x_j = a_1 x_1 + a_2 x_2 ,
$$

(2)

where: $a_1 = (2 - B)\cos^2(\alpha) - 0.5B\sin(2\alpha)$, $a_2 = (2 - B)\sin(2\alpha) + B\cos(2\alpha)$, $x_1 = \sigma_x$, $x_2 = \tau_{xy}$. 

From theory of probability [6] it results that the variance of random variable being a linear function of some random variables is expressed by the following formula

$$\mu_{req} = \sum_{j=1}^{n} a_j^2 \mu_{x_j} + 2 \sum_{j \neq k} a_j a_k \mu_{x_{jk}} = a_1^2 \mu_{x_1} + a_2^2 \mu_{x_2} + 2a_1a_2 \mu_{x_1x_2},$$

(3)

where: \( \mu_{req} \), \( \mu_{x_1} \), \( \mu_{x_2} \) - variance of equivalent stress \( \sigma_{eq} \), normal stress \( \sigma_x \) and shear stress \( \tau_{xy} \), respectively, \( \mu_{x_{1x2}} \) - covariance of normal \( \sigma_x \) and shear \( \tau_{xy} \) stresses.

Under biaxial random stationary and ergodic stress state, the variances \( \mu_{x_1}, \mu_{x_2} \) and the covariance \( \mu_{x_{1x2}} \) in Eq. (3) are constant.

In the method of variance for determination of the critical plane position the maximum function of Eq. (3) is searched in relation of the angle \( \alpha \) occurring in coefficients \( a_1 \) and \( a_2 \). After reduction, the variance of equivalent stress \( \mu_{req} \) versus the angle \( \alpha \) can be written as

$$\mu_{req} = \left[ (2-B)\cos^2(\alpha) - 0.5B\sin(2\alpha) \right] \mu_{x_1} + \left[ (2-B)\sin(2\alpha) + B\cos(2\alpha) \right] \mu_{x_2}$$

+ $$2\left[ (2-B)\cos^2(\alpha)B\cos(2\alpha) + (2-B)\sin(2\alpha) \right] - 0.5B \left[ (2-B)\sin^2(2\alpha) + 0.5B\sin(4\alpha) \right] \mu_{x_1x_2}. \tag{4}$$

In the method of damage accumulation the damage degree \( S_{PM}(T_O) \) during observation time \( T_O \) was calculated with use of the rain flow algorithm and Palmgren-Miner hypothesis

$$S_{PM}(T_O) = \begin{cases} \sum_{i=1}^{k} \frac{n_i}{N_0 \left( \frac{\sigma_{af}}{\sigma_{eq,ai}} \right)^m} ; & \text{for } \sigma_{eq,ai} \geq a \cdot \sigma_{af} \\ 0; & \text{for } \sigma_{eq,ai} < a \cdot \sigma_{af} \end{cases}, \tag{5}$$

where: \( \sigma_{eq,ai} \) - amplitude of the equivalent stress, \( m \) – coefficient of Wöhler’s curve slope, \( \sigma_{af} \) – fatigue limit under bending, \( N_0 \) – number of cycles corresponding to the fatigue limit \( \sigma_{af} \), \( n_i \) – number of cycles with amplitude \( \sigma_{eq,ai} \), \( a \) – coefficient allowing to include amplitudes below the fatigue limit in the process of fatigue damage accumulation (\( a = 0.5 \) was assumed in this paper), \( k \) – number of intervals of the amplitude histogram.

Fatigue life \( T_{cal} \) was calculated according to the following equation

$$T_{cal} = \frac{T_O}{S_{PM}(T_O)}. \tag{6}$$

According to the method of damage accumulation, the critical plane position is identified by the maximum damage.

Graphs in Figs. 2a – 14a present relation between the normalized value of equivalent stress variance (see Eq. (4)), while graphs in Figs. 2b – 14b show relation between the normalized value of the damage degree (see Eq. (5)) and the critical plane angle \( \alpha \), respectively. The pseudo-random loadings generated the same cross-correlation coefficient between normal and shear stresses \( r_{xy} = 0.16 \) and different ratios of maximum stresses \( \lambda_{xy} = \tau_{xy,max} / \sigma_{x,max} \).

From Figs. 2–14 it appears that the variance of equivalent stress \( \mu_{req} \) and the fatigue damage degree \( S_{PM}(T_O) \) are continuous function of the critical plane angle \( \alpha \) with some maximum values. Taking into account a certain randomness of the material structure and assuming that the critical plane
position can occur at 5% deviation from the maximum variance and the maximum damage degree, ranges of variation of the angle $\alpha$ for particular loading cases can be distinguished (Table 2).

(*) Angles $\alpha_{FP}$ and $\alpha_\tau$ may be positive or negative – it depends on point of view

Fig.2. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K01 ($\lambda_{\sigma} = 0.189$).
While experiments, two kinds of crack planes could be seen. One of them occurred at the stage I (crack initiation), the other one occurred at the stage II (crack propagation, fracture plane). The initiation plane is inclined to the propagation plane at the angle of $45^\circ$.

Fig. 3. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K02 ($\lambda_{\text{cr}} = 0.274$).

Fig. 4. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K03 ($\lambda_{\text{cr}} = 0.358$).

Fig. 5. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K04 ($\lambda_{\text{cr}} = 0.442$).
Fig. 6. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K05 ($\lambda_\sigma = 0.214$).

Fig. 7. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K06 ($\lambda_\sigma = 0.309$).

For the cases K01-K08 in Table 2, the crack initiation plane (stage I) obtained from experiments coincides with the results of calculations with the variance method. A poor conformity of the experimental and calculated results was obtained by means of the method of damage accumulation. There is one case K07, which confirms calculation and experimental results. However, there were the cases K09-K13 where the crack initiation plane obtained from experiments did not coincide with that defined from the calculations.

Fig. 8. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K07 ($\lambda_\sigma = 0.405$).
Fig. 9. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K08 ($\lambda_\alpha = 0.5$).

Fig. 10. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K09 ($\lambda_\alpha = 0.394$).

For the cases K10 and K13 the crack propagation plane (stage II) obtained while experiments coincided with the calculation results obtained by means of the variance method and the method of damage accumulation. The critical plane angle ranges $\Delta\alpha$ (with 5% variation of $\alpha$) according to the variance and damage accumulation methods overlap in almost all cases except two K05 and K09.

Test measurements of the fracture plane angle $\alpha_{FP}$ (stage II) were performed on the specimen surface with the optical method (magnification 10x) to an accuracy of $1^\circ$, and the scatter band of the

Fig. 11. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K10 ($\lambda_\alpha = 0.515$).
Fig. 12. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K11 ($\lambda_\alpha = 0.636$).

Fig. 13. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K12 ($\lambda_\alpha = 0.68$).

Experimental results was shown in Table 2. The angle of the plane position was determined from linear approximation with the least square method. Measurement of the angle $\alpha_{FP}$ was done for the stage II (propagation), and the angle $\alpha_{c}$ for the stage I (initiation) was obtained by the plane rotations by the angle of $45^\circ$.

Fig. 14. Dependence of the normalized value of: a) variance, b) damage accumulation on the angle $\alpha$ of critical plane position for loading combination K13 ($\lambda_\alpha = 0.84$).

Figure 15 shows differences in experimental and calculated fatigue lives with critical planes determined according to variance and damage accumulation methods. In spite of differences in
angle of critical plane position fatigue lives are almost the same for both methods. Determination of the critical plane with the method of variance is connected only with the stress values, while the method of damage accumulation includes also characteristics of the fatigue strength of the given material.

Fig.15. Comparison of experimental and calculated fatigue lives according to the failure criterion of maximum normal and shear stresses in the critical planes determined with: a) variance and b) damage accumulation methods.

Summary
The normalized values of the equivalent stress variance and damage accumulation depending on the angle of the critical plane position $\alpha$ are different for different combinations of loading. The method of variance gives the angles more similar to the experimental data for the initiation plane position (stage I). The variance and damage accumulation methods indicate the critical plane angle ranges (with 5% variation of angle) which overlap in almost all 13 analysed cases of pseudo-random loadings except two. A conformity of the experimental fatigue life with the calculated results was obtained by means of the failure criterion of maximum normal and shear stress in the critical plane according to the both variance and damage accumulation methods.
