ABSTRACT. Elastic-plastic crack growth under mixed mode I and II in aluminum alloys and steels were investigated. Two approaches are developed for geometrical modelling of crack growth trajectories for the central notched and compact tension shear specimens respectively. The damage process zone size concept is used for calculations of mixed-mode crack path. The influence of specimen geometry, biaxial loading and properties of the aluminum alloys and the steels on both crack growth direction and crack path at the macroscopic scale is discussed.

INTRODUCTION

Main feature of mixed-mode fracture is that the crack growth would no longer take place in a self-similar manner and does not follow a universal trajectory that is it will grow on a curvilinear path. It is known that a “bent” crack does not propagate in its initial orientation direction. For mixed mode crack propagation, the crack front is continuously changing shape and direction with each loading cycle. As a result, the angle of crack propagation $\theta_*$ changes continuously. At each successive position of the crack front, the stress intensity factors in a plate, $K_1$ and $K_2$, must be calculated. However, for the actual “bent” crack geometry, the expressions for $K_1$ and $K_2$ cannot be easily determined. To overcome this difficulty an approximate procedure has been used by many authors (see Refs. [1]). Essentially, the procedure involves replacing the bent crack with a straightline crack approximation. A fatigue crack may be assumed to grow in a number of discrete steps. From the given initial values of crack angle $\beta$, biaxial ratio $\eta$ and crack length $a$, the crack deviation angle $\theta_*$ is determined by the crack growth direction criterion. After each increment of crack growth, the crack angle changes from the original angle $\beta$ and so does the effective length of the crack. For the next increment of crack growth, one has to consider the new crack length $a_i$ and crack angle $\beta_i$. Values of $a_i$ and $\beta_i$ can be determined using the vectorial method. The objective of the present paper is to computationally and experimentally study crack growth under Mixed-Mode I and II loading in central notched and compact tension shear specimens.
THEORETICAL AND METHODICAL ASPECTS

The experimental part of our work is performed on plane compact tension shear (Fig.1,a) and eight-petal specimens (Fig.1,b). The first two specimen configurations with single-edge and central initial cracks were tested under uniaxial loading with variation of the initial crack orientation angle relative to the loading axis. Compact tension shear specimens are made from 30Cr steel types A, B and C (see Table 1) and used for mixed-mode fracture test with the loading direction to an angle $\beta_0$ to the initial crack plane. Values of $\beta_0$ are varied from 0° up to 90°. Non self-similar crack growth is realized in the compact tension shear specimen by using a set of S-shaped grips developed by Richard [2] such that a different mixity parameter, $M_E$ or $M_F$, can be obtained corresponding to the different proportions of tensile and shear loads. The mixed-mode parameter, $M_E$, expressed through the Mode I and Mode II stress intensity factors, was varied by changing the load direction, $\beta_0$. Specimens were precracked under cyclic loading until they reached a crack length of $a_0 = 44$ mm. After the precrack had been created, each specimen was subjected to a different mixed mode fatigue load. As a result of cyclic mixed mode loading a branched fatigue crack is formed as it is shown in Fig.1,a.

![Figure 1. Compact tension shear (a) and eight-petal (b) specimens tested at different mixed mode loading](image)

Eight-petal specimens (Fig.1,b) are made from aluminum alloys (see Table 1) and used for biaxial test. Mixed-mode fracture tests under biaxial loading with stress ratio $\eta = 0.5$ are performed such that the mixed mode parameter, $M_E$, was varied by changing the inclined angle of initial crack, $\beta_0$, from 0° up to 90°. Using the specimen with a slant crack any desired $K_1$ and $K_2$ combinations can be induced by various both crack
angle and biaxial loadings. In our work the experimental results on the 30Cr steel types A,B,C and eight aluminum alloys are used to compare with the computational data. Their main mechanic characteristics are presented in Table 1. The tests were carried out at the room temperature under cycle loading.

Here σ₀ is the yield stress, σₜ is the tensile strength, σₖ is the true fracture stress, εₖ is the true fracture strain, n is the strain hardening exponent.

Many of the fracture mechanics theories are based on a critical distance local to the crack tip. It has been considered as fundamental characteristic parameter that distinguishes damage at the microscopic and macroscopic scale level. Within the fracture damage zone some microstructural damage accumulates until crack growth takes place at the macroscopic scale level. In the present paper the critical distance rᵣ ahead of the crack tip is assumed to be located where the stress strain state in the element reaches a certain critical value that can be measured from a uniaxial test. A relative fracture damage zone size $\delta_c = r_c/a$ was introduced by Shlyannikov [3]

$$\delta_c = \left\{ \frac{S_2 \pm S^2_2 - 4(W^* - S_3)(S_f + S_p)}{2(W^* - S_3)} \right\}^2$$

where $W^* = \left( \frac{\sigma_0}{\sigma_{yn}} \right)^2 \left[ \frac{1}{2}S_f^2 + \frac{\alpha n}{n+1} \bar{\sigma}_{n+1}^2 \right]$ and $\bar{\sigma}_f \approx \bar{\sigma}_{u}^\text{true} = \frac{\sigma_u}{\sigma_0} (1 - \psi)$

All stresses in these equations are normalized by the yield stress $\sigma_0$, and $\sigma_u$ is the true ultimate tensile stress, $\psi$ is the reduction of area. In equation (1) $S_i (i = 1,2,3)$ and
\( \bar{S}_p \) are elastic and plastic coefficients respectively. The work [3] contains more details about the determination of these coefficients \( \bar{S}_l = \bar{S}_l(\theta, \kappa, \beta, \eta, Y_f, Y_H) \) and \( \bar{S}_p = \bar{S}_p(n, \nu, I_n, M_P, \bar{\sigma}_e, Y_f, Y_H) \) for the general case of mixed-mode elastic-plastic fracture. These coefficients are different for various geometric configurations. Thus, the radial distance \( r_c \) normalized by the crack length \( a \) may be found from relation (1) to be a function of the angular direction \( \theta \), the material properties, the stress strain state and the mixed-mode parameter \( M_p \).

When calculating the crack growth trajectory it is necessary to distinguish the following principal moments. Firstly, proceeding from theoretical precondition one can estimate the crack front shape as a set of successive positions of the assumed crack tip on its propagation trajectory, as was made by Shlyannikov and Dolgorukov [4]

\[
\left\{ \begin{align*}
\Delta a_i &= \left[a_i^2 + \Delta a_{i-1}^2 - 2a_i \Delta a_{i-1} \cos(\pi - \theta_{i-1}^*)\right]^{1/2} \\
\beta_i &= \beta_{i-1} \arcsin \left[\frac{\Delta a_i \sin(\pi - \theta_{i-1}^*)}{a_i}\right]
\end{align*} \right. \tag{3}
\]

where \( \theta_{i-1}^* \) is crack growth direction or crack deviation angle. Secondly, in fatigue life calculations it is necessary to connect the crack length increment \( \Delta a_i \) along its growth trajectory with the corresponding number of loading cycles \( \Delta N_i \).

Let \( \Delta a_i \) in Eq. 3 have the physical sense of the fracture damage zone size \( \delta_i \). Then Eq.1 can be applied to the crack path prediction for the two typical geometric configurations containing the single-edge and the central initial cracks of length \( a_0 \) and obliqueness \( \beta_0 \) as shown in Fig.2,a and b. Crack path prediction for the mixed modes I and II initial crack can be carried out making use of the following scheme. This scheme involves replacing a bent crack with a straightline crack approximation, as shown in Fig.2. The principal feature such modeling is determination of the crack growth direction and definition of crack length increment in this direction. Crack may be assumed to grow in a number of discrete steps. After each increment of crack growth, the crack angle changes from the original angle \( \beta_0 \) and so does the effective length of the crack. For the next increment of crack growth, one has to consider the new crack length \( a_i \) and crack angle \( \beta_i \). As shown in Fig.2, OA is the initial crack length \( a_0 \) oriented at an angle \( \beta_0 \). Let \( r_0 = AB \) be the crack growth increment for the first growth step. It would correspond to the fracture damage zone size. Making use of Eq.1, \( \delta \) and hence \( r_0 = \delta a_0 \) can be computed. The value \( r_0 \) is then extended along AB with the angle \( \theta_0^* \) whose value is determined by the crack growth direction criterion. For the single-edge crack geometry (Fig.2,a) the first step of crack growth obtained as \( \phi_0 = \theta_0^* \) and

\[
x_0 = r_0 \cos \theta_0^*, \quad y_0 = r_0 \sin \theta_0^* \tag{4}
\]
Figure 2. Crack growth trajectory approximation, (a) single-edge crack geometry, (b) central notched biaxially loaded crack geometry.

The next step plotting $r_i$ along BC oriented at the angle $\theta_i^\ast$. In this case $AC=\sqrt{\sum x^2 + \sum y^2}$ and

$$\phi_i = \tan^{-1}\left(\frac{y}{x}\right), \quad x_i = r_i \cos \gamma_i, \quad y_i = r_i \sin \gamma_i$$

where

$$\gamma_i = \Delta \beta_i + \theta_i^\ast, \quad \sum x = x_0 + x_1, \quad \sum y = y_0 + y_1$$

and so on. For the central crack geometry subjected to biaxial loads (Fig. 2, b) the crack path can be determined using the formulae Eq. 1.
RESULTS AND DISCUSSION

In this section the experimental results on the 30Cr steel types A,B,C and eight aluminum alloys are used to compare with the computational data. Criterion [1] is applied for analyzing the fatigue crack growth trajectories in specimens the above geometries. On the compact tension shear specimen was realized the full range of mixed mode fracture from tensile (pure Mode I) to shear (pure Mode II) loading. The eight petal specimens are subjected to biaxial tension at $\eta=0.5$ as the initial inclination angle, $\beta_0$, is varied from $0^\circ$ up to $90^\circ$.

Figures 3,a-d present a comparison of both computational and experimental crack growth trajectories for aluminum materials and 30Cr steel with different properties subjected to biaxial and uniaxial tension at $\eta=0.5$ and $\eta=0.0$, respectively. Their conformity suggests the validity of the straightline crack concept and hence Eqs.3 may be used in fatigue life calculations. A characteristic feature of Eq.3 as against other equations in Refs [1] is the fact that they take into account an influence of both the materials properties (strain hardening exponent) and the nominal stress $\sigma$ on the crack growth trajectory via the angle of crack propagation $\theta^\circ$. As it is shown in Fig.3,a the fatigue trajectories under uniaxial and biaxial tension for brittle aluminum alloy 01419 almost coincide. However, for ductile aluminum alloy AMG6 the crack paths under the same types of loading are very different. Under uniaxial tension when these cracks propagate, they gradually rotate to align normal to the applied principal stress directions.

Brittle and ductile materials have different curvature of the crack trajectories. This is confirmed by the experimental results that are presented in Fig.3,b. The occurrence of mixed mode growth is dictated by the crack angle, but the occurrence of any mode is believed to be dependent on both stress state and microstructure. Usually when viewed on the macroscopic scale with respect to the material structure the fatigue crack path may generally be regarded as smooth. However, on smaller, microscopic scale, the crack path is generally very irregular. It can be noted that our approach based on the of fracture damage zone concept allows to describe the crack behavior on the microscopic scale.

In the experimental and computational data presented in Fig.3,b the following may be mentioned. Under the same biaxial loading conditions the crack trajectory for some materials tends to be normal to the nominal tensile stress $\sigma_{\text{nm}}$ direction, while for others this does not occur. This distinction on crack growth trajectories is connected with different properties of materials. Numerical and experimental results concerning the effect of the (a/w)-variation showed for compact tension shear specimens (Fig.3,c,d) that the fatigue crack path is sensitive to both the initial crack orientation and length change.

In Fig.4 initial parts of the fatigue crack path corresponding to macrotrajectories displayed in Fig.3,b for $\eta=0.5, \beta_0=0^\circ$ and $\beta_0=65^\circ$ are presented, respectively. As it is seen in Fig.4 the degree of irregularity in crack path depends on the initial inclination
angle, $\beta_0$. So, the situation in biaxially loaded eight-petal specimen for $\eta=0.5$ and $\beta_0=0^\circ$ (or $\eta=2$ and $\beta_0=90^\circ$) concerns the state of unstable equilibrium, and the irregularity in crack behavior is greater than for $\beta_0=65^\circ$. The zig-zag path of a propagating crack may be explained by considering the advancement of a crack as consisting of distinctive steps, where voids and other discontinuities of the material, surrounding the crack tip, coalesce and create each kink for the crack. If the biaxial stresses are tensile ($\eta>0$) then a crack is directionally unstable and, following a small
deviation, does not return to its initial plane. A crack, for example, in a eight-petal specimen under biaxial tension with $\eta=0.5$ and $\beta_0=0^\circ$ is directionally unstable in this sense, and a typical crack path is shown in Fig.4.a. Moreover, for these specimens under biaxial loading the amount of crack path curvature (Fig.4,b) is a function of the tensile properties of the aluminum alloys concerned Table 1.

![Figure 4](image)

Figure 4. Computational predictions for the fatigue crack path at the microscale level

Thus, the influence of the geometry specimens, the initial crack length and the material properties were studied. Attention is focused on the mixed-mode crack trajectories. The behavior of the crack path under mixed-mode fracture is discussed with regard to microscopic and macroscopic scales.
